Abstract

On some level, human sentence comprehension must involve both memory retrieval and structural composition. This study differentiates these two processes using neuroimaging data collected during naturalistic listening. Retrieval is formalized in terms of “multiword expressions” while structure-building is formalized in terms of bottom-up parsing. The results most strongly implicate Anterior Temporal regions for structure-building and Pre-cuneus Cortex for memory retrieval.

1 Introduction

This study differentiates processes of structure-building and memory retrieval in the brain, as they occur during naturalistic language comprehension. We use multiword expressions to investigate this distinction. The term itself comes from computational linguistics; roughly it means expressions that are better treated non-compositionally (Sag et al., 2002). Figure 2 on page 2 highlights several examples.

MWEs raise an important theoretical question about language processing, namely the balance between productivity and reuse (Goldberg, 2006; Jackendoff, 2002; O’Donnell, 2015). If MWEs indeed lack internal structure, then perhaps their comprehension proceeds through a single, unitary memory retrieval operation, rather than some kind of multi-step composition process. Proceeding from this hypothesis, the paper contributes a localization of these two cognitive processes in the brain through an analysis of fMRI timecourses collected during naturalistic listening.

2 Memory Retrieval vs. Structure-building

The name MWE loosely groups a wide variety of linguistic phenomena including idioms, perfunctory greetings and personal titles.

(1) When I drew the baobabs, I was spurred on by a sense of urgency

(2) “Good morning”, said the little prince politely, who then turned around, but saw nothing.

The syntactic or semantic properties of the bold-faced expressions cannot be derived just from their parts and in some way, they are conventionalized. They are plausibly stored, rather than built on the fly (Cacciari, 2014).

By contrast, other expressions are less likely to have been explicitly memorized and therefore call for some degree of structural composition, in comprehension. This sort of processing can be formalized using parsing algorithms (Hale, 2014). Figure 1 on page 2 indicates the number of reduce steps that a bottom-up parser would take, word-by-word, as it builds the depicted phrase structure. Our analysis of the neuroimaging data described in the next section takes this number as an index of structure-building effort.

3 fMRI Study

3.1 Method

We follow Brennan et al. (2012) in using a spoken narrative as a stimulus. Participants hear the story over headphones while they are in the scanner. The
sequence of neuroimages collected during their session becomes the dependent variable in a regression against word-by-word predictors, derived from the text of the story.

### 3.2 Stimuli

The audio stimulus was Antoine de Saint-Exupéry’s *The Little Prince*, translated by David Wilkinson and read by Nadine Eckert-Boulet.

Within this text, 1,274 MWEs were identified using a CRF tagger. This tagger was trained on examples from the English Universal Dependency treebank, in combination with external lexicons as suggested by Constant and Tellier (2012). The tagger used feature templates, as seen in Table 1 below, where \( w_t \) stands for the token at the relative position \( t \) from the current token and \( l_0 \) is the label at the relative position \( t \). The external lexicons included the Unitex lexicon (Paumier et al., 2009), SAID corpus (Kuiper et al., 2003), Cambridge International Dictionary of Idioms (White, 1998), and Dictionary of American Idioms (Makkai et al., 1995).

Among these MWEs, attestation rates for particular subtypes are given in Table 2.

### 3.3 Participants

Participants were forty-two volunteers (26 women and 16 men, 18-37 years old) with no history of...
psychiatric, neurological, or other medical illness or history of drug or alcohol abuse that might compromise cognitive functions. All qualified as right-handed on the Edinburgh handedness inventory (Oldfield, 1971). They self-identified as native English speakers and gave their written informed consent prior to participation, in accordance with Cornell University IRB guidelines.

### 3.4 Presentation

After giving their informed consent, participants were familiarized with the MRI facility and assumed a supine position on the scanner gurney. The presentation script was written in PsychoPy (Peirce, 2007). Auditory stimuli were delivered through MRI-safe, high-fidelity headphones (Confon HP-VS01, MR Confon, Magdeburg, Germany) inside the head coil. The headphones were secured against the plastic frame of the coil using foam blocks. Using a spoken recitation of the US Constitution, an experimenter increased the volume until participants reported that they could hear clearly. Participants then listened passively to the audio storybook for 1 hour 38 minutes. The story had nine chapters and at the end of each chapter the participants were presented with a multiple-choice questionnaire with four questions (36 questions in total), concerning events and situations described in the story. These questions were used to confirm their comprehension and were viewed by the participants via a mirror attached to the head coil and they answered through a button box. The entire session lasted around 2.5 hours.

### 3.5 Data Collection

Imaging was performed using a 3T MRI scanner (Discovery MR750, GE Healthcare, Milwaukee, WI) with a 32-channel head coil at the Cornell MRI Facility. Blood Oxygen Level Dependent (BOLD) signals were collected using a T2-weighted echo planar imaging (EPI) sequence (repetition time: 2000 ms, echo time: 27 ms, flip angle: 77deg, image acceleration: 2X, field of view: 216 x 216 mm, matrix size 72 x 72, and 44 oblique slices, yielding 3 mm isotropic voxels). Anatomical images were collected with a high resolution T1-weighted (1 x 1 x 1 mm\(^3\) voxel) with a Magnetization-Prepared RApid Gradient-Echo (MP-RAGE) pulse sequence.

### 4 Data Analysis

#### 4.1 Preprocessing

fMRI data is acquired with physical, biological constraints and preprocessing allows us to make adjustments to improve the signal to noise ratio. Primary preprocessing steps were carried out in AFNI version 16 (Cox, 1996) and include motion correction, coregistration, and normalization to standard MNI space. After the previous steps were completed, ME-ICA (Kundu et al., 2012) was used to further preprocess the data. ME-ICA is a denoising method which uses Independent Components Analysis to split the T2*-signal into BOLD and non-BOLD components. Removing the non-BOLD components mitigates noise due to motion, physiology, and scanner artifacts (Kundu et al., 2017).

#### 4.2 Statistical Analysis

The GLM typically used in fMRI is a hierarchical model with two levels (see Poldrack et al., 2011). At the first level, the data for each subject is modelled separately to calculate subject-specific parameter estimates and within-subject variance such that for each subject, a regression model is estimated for each voxel against the time series. The second-level model takes subject-specific parameter estimates as input. It uses the between-subject variance to make statistical inferences about the larger population.

The GLM analysis was performed using SPM12 (Penny et al., 2011). The following regressors were used. One regressor formalizes structure-building using a standard bottom-up parsing algorithm (see chapter 3 of Hale, 2014). We computed the number of parser actions that would be required, word-by-word, to build the correct phrase structure tree as determined by the Stan-
ford parser (Klein and Manning, 2003). Another regressor formalizes memory retrieval, by marking multiword expressions (MWE; see section 3.2). Each word in the text was annotated with a 0 or 1, depending on whether it was the last word of a MWE. This coding scheme expresses the idea that a different process occurs at the end of multiword expressions, and this provisionally assumes a very conservative approach to the Configuration Hypothesis (Cacciari and Tabossi, 1988; Tabossi et al., 2009). We regressed the word-by-word predictors described above against fMRI timecourses recorded during passive story-listening in a whole-brain analysis. Along with the parsing and MWE regressors of theoretical interest, we entered four “nuisance” variables or regressors of non-interest into the GLM analysis using SPM12. One regressor simply marks the offset of each spoken word in time. Another gives the log-frequency of the individual word in movie subtitles (Brysbaert and New, 2009). The last two reflect the pitch (f0) and intensity (RMS) of the talker’s voice. These nuisance regressors are added to the GLM analysis to improve sensitivity, specificity and validity of activation maps (Bullmore et al., 1999; Lund et al., 2006). In particular, we sought to ensure that any conclusions about parsing and memory retrieval would be specific to those processes, as opposed to more general aspects of speech perception.

5 Results

In the second-level group analysis, bottom-up parsing and multi-word expressions were analyzed separately. Results are presented below in Tables 3 and 4 using region names from the Harvard-Oxford Cortical Structure Atlas.

### 5.1 Group level results for bottom-up parsing

Table 4: Significant clusters for MWEs after FWE voxel correction

The largest clusters (p < 0.05 FWE) were observed in Precuneus Cortex and Frontal regions.

Figure 3: T-score map for the Bottom-up Parser action count regressor. Red represents the positive score while blue represents the negative score.
Figure 4 (also plotted with nilearn) is the T-score map for the MWE status regressor, which is meant to formalize the retrieval of these noncompositional expressions.

6 Discussion

The operationalization of structure-building as bottom-up parsing highlights Anterior Temporal as well as Frontal regions. These results are consistent with earlier work including deficit-lesion data (Dronkers et al., 2004), fMRI studies of text comprehension (Ferstl et al., 2008), and magnetoencephalography studies of phrasal composition (Bemis and Pyllkänen, 2011). This literature also confirms the sensitivity of Anterior Temporal regions to parametric variation of phrase size (Pallier et al., 2011).

With respect to MWEs, significant activation was observed in the Precuneus. The Precuneus has not traditionally been viewed as part of the language network. However, it has been designated as part of the Protagonist’s Perspective Interpreter Network (Mason and Just, 2006). This network in fact appears to be activated by many different sorts of story characters, not just the protagonist (Wehbe et al., 2014). Along these lines, the Precuneus activation in Figure 4 might be interpreted narrowly as an effect of reference to dramatis personae in the narrative stimulus. This restricted interpretation would be challenged by the fact that less than 25% of the MWEs in the stimulus text are references to story characters. To account for the full collection, including verbal MWEs, a more general characterization in terms of memory retrieval seems appropriate.

This more general characterization is bolstered by data that implicate the Precuneus in memory tasks:

- Verbal memory (Halsband et al., 2002)
- Spatial memory (Wallentin et al., 2008)
- Episodic memory (Andreasen et al., 1995)
- Memory-related imagery (Fletcher et al., 1995; Mashal et al., 2014)

As Spreng et al. (2009) suggest, the Precuneus could be part of a wider, task-general network that is also recruited in Theory-of-Mind, Prospection and Autobiographical memory tasks. These considerations strengthen the interpretation, based on MWEs, that the Precuneus mediates memory retrieval during naturalistic language comprehension.

The findings as a whole are broadly consistent with existing neurocognitive models of language. For example, within Hagoort’s (2016) MUC model, MWE comprehension might tap memory resources, whereas bottom-up parsing might involve unification. With MUC, our analysis suggests a localization of these memory resources to the Parietal lobe. Within the Procedural/Declarative model (Ullman, 2001; 2004), rule-based linguistic knowledge would be localized to Frontal regions. This is consistent with the Frontal activations that we observe in response to the bottom-up parsing regressor.

7 Conclusion

These results point to a spatial differentiation between reuse and composition in language comprehension. Reuse, here operationalized with multi-word expressions, seems to involve the Precuneus. Composition, in the sense of phrase-structure parsing, seems to call upon Anterior Temporal areas.
