Expected Classification Accuracy

Lawrence M. Rudner
Graduate Management Admission Council

Every time we make a classification based on a test score, we should expect some number of misclassifications. Some examinees whose true ability is within a score range will have observed scores outside of that range. A procedure for providing a classification table of true and expected scores is developed for polytomously scored items under item response theory and applied to state assessment data. A simplified procedure for estimating the table entries is also presented.

Given a test composed of N items used to classify examinees into one of K score groups, what percent of examinees can we expect to be classified properly? A procedure for computing expected classification accuracy for dichotomous items (Rudner, 2001) is extended to polytomous items and applied in this paper. A simple procedure for estimating accuracy based on data appearing in technical reports is also presented.

By definition, for any given true score, \( \theta \), the corresponding observed score, \( \hat{\theta} \), is expected to be normally distributed, with a mean of \( \bar{\theta} \) and a standard deviation of \( se(\theta) \). The probability of an examinee with a given true score of \( \theta \) having an observed score in the interval \([a, b]\) on the theta scale is then

\[
\text{Prob}(a < \hat{\theta} < b | \theta) = \phi\left(\frac{b - \theta}{2se(\theta)}\right) - \phi\left(\frac{a - \theta}{2se(\theta)}\right)
\] (1)

where \( \phi(z) \) is the cumulative normal distribution function. This is the area under the normal curve between a and b with mean \( \theta \) and standard deviation \( se(\theta) \).

Multiplying equation (1) by the expected proportion of examinees whose true score is \( \theta \) yields the expected proportion of examinees whose true score is \( \theta \) expected to be in interval \([a, b]\). Summing or integrating over all examinees in interval \([c, d]\) yields the expected proportion of all examinees that have a true score in \([c, d]\) and an observed score in \([a, b]\):

\[
\sum_{\theta=c}^{d} P(a < \hat{\theta} < b | \theta) f(\theta)
\]

where \( f(\theta) \) is the expected proportion of examinees whose true score is \( \theta \). If we assume \( \theta \) is \( N(\mu, \sigma) \) then \( f(\theta) \) is the standard normal density function \( \varphi(z) \).

Setting \([a, b]\) and \([c, d]\) to correspond to the true score intervals defined by the cut scores yields the elements of a classification table showing the expected proportion of all examinees with observed and true scores in each cell. The individual elements of the classification table are:
Practical Assessment Research & Evaluation, Vol 10, No 13

Rudner, Expected Classification Accuracy

\[
\sum_{\theta=0}^{d-1} P(a < \theta < b | \theta) f(\theta) =
\]

\[
\sum_{\theta=0}^{d} \left( \phi \left( \frac{\theta - \mu}{\sqrt{\sigma^2(\theta)}} \right) - \phi \left( \frac{\theta - \mu}{\sqrt{\sigma^2(\theta)}} \right) \right) f(\theta)
\]

(2)

where \( f(\theta) \) is the expected proportion of examinees whose true score is \( \theta \). One computes equation (2) for each cell to obtain the complete \( K \times K \) classification table. Overall accuracy, then, is the sum of the diagonal entries.

**Example**

Table 1 contains the item parameters for the 10-item 2001 Maryland State Performance Assessment Program Grade 8 Reading Test, Form A. The test was calibrated and scored by CTB-McGraw Hill using the generalized partial credit model (Muraki, 1992). The \( K=5 \) score intervals are \((375,489), (490,529), (530,579), (580,619), (620,650)\). Mean and standard deviation were originally set to be 500 and 50.

**Table 1: Generalized Partial Credit Model Item Parameters for a 10-Item Reading Test**

Because the standard error at theta is the reciprocal of the square root of the Test Information Function at theta, the Test Information Function is the sum of the Item Information Function, and under the generalized partial credit model (Donoghue, 1994), the Item Information Function is

\[
I_i(\theta) = a_i^2 \left[ \sum_{k=0}^{d} k^2 P_{ik}^2(\theta) \right] - \left( \sum_{k=0}^{d} k P_{ik}(\theta) \right)^2
\]

where \( a_i \) is the item discrimination index, the standard error for a given value of theta is:

\[
s_e(\theta) = \left[ \sum_{k=0}^{d} \left( kP_{ik}(\theta) \right)^2 \left( \sum_{k=0}^{d} k^2 P_{ik}^2(\theta) \right) \right]^{1/2}
\]

(3)

Using Table 1 and equations (2) and (3) yields the classifications shown in Table 2. The sum of the diagonals in Table 2, 81.4%, is the expected accuracy. In this case, the testing agency recognized that the accuracy of individual scores would not be sufficiently high and only reported aggregated test scores. An examination of the marginals reveals that the expected proportion of examinees in each category never differs from the true score category by more than .5%. Thus this 10-item test appears sufficient for reporting aggregated scores.

A Simplified Estimate

The test contractor routinely provides the standard errors at the different cut scores. By making the convenient assumption that the standard errors are linear within a range, one can compute an estimated $\text{se}(\theta)'$ as a linear extrapolation of the values provided by the contractor:

$$\text{se}(\theta)' = \frac{\theta - a}{b - a} (\text{se}_b - \text{se}_a) + \text{se}_a \quad (4)$$

where $a$ and $b$ are adjacent cut scores on the theta scale and $\text{se}_b$ and $\text{se}_a$ are the corresponding standard errors.

This allows one to make a simple estimate of accuracy using equation (4) rather than the more complex equation (3). For the test in our example, the standard errors at scaled scores of 375, 490, 530, 580, 620, and 650 are 60, 11, 12, 26, 57, and 106 respectively. Using these values, along with Table 1 and equations (3) and (4), yields the following estimated expected truth table.

The sum of the diagonals is 78.0% which is fairly close to the first estimate. The advantage of this approach is that one does not need to compute the probabilities of selecting option k for each item.

DISCUSSION

The accuracy of a test is usually gauged by summing across all possible scores, e.g., root mean square and goodness-of-fit. Yet if one is only interested in estimating the proportion of students mastering a content area or the proportions of students in a discrete category, then categorical analysis might be more appropriate. This paper presented a categorical approach. In this case, a 10-item test provided accurate classifications 81% of the time. The estimated and actual proportions of examinees in each score interval never differed by more than .5%.

</tbody>
</table>

One can use this approach to estimate accuracy with different numbers of items. If we halve the standard errors, possibly by using much better items or more likely by lengthening the test length, accuracy would increase to 91%. That value might be adequate for many purposes. Reducing the standard errors four-fold would yield an expected classification accuracy of 95% - an improvement that may or may not be worth the additional cost.
