Abstract—The sheer volume of data generated by depth cameras provides a challenge to process in real time, in particular when used for indoor mobile robot localization and navigation. We introduce the Fast Sampling Plane Filtering (FSPF) algorithm to reduce the volume of the 3D point cloud by sampling points from the depth image, and classifying local grouped sets of points as belonging to planes in 3D (the “plane filtered” points) or points that do not correspond to planes within a specified error margin (the “outlier” points). We then introduce a localization algorithm based on an observation model that down-projects the plane filtered points onto 2D, and assigns correspondences for each point to lines in the 2D map. The full sampled point cloud (consisting of both plane filtered as well as outlier points) is processed for obstacle avoidance for autonomous navigation. All our algorithms process only the depth information, and do not require additional RGB data. The FSPF, localization and obstacle avoidance algorithms run in real time at full camera frame rates with low CPU requirements at more than 1030 frames per second on average. We provide experimental results demonstrating the effectiveness of our approach for indoor mobile robot localization and navigation. We further compare the accuracy and robustness in localization using depth cameras with FSPF vs. alternative approaches which simulate laser rangefinder scans from the 3D data.

I. INTRODUCTION

The recent availability of inexpensive depth cameras has made available dense 3D point clouds, which were previously only accessible using much more expensive sensors like time-of-flight cameras or scanning 3D laser rangefinders. We are interested in using these depth cameras for ground based indoor mobile robots. We consider mobile robots with limited onboard computational power, and address two immediate challenges to using the depth cameras for mobile robot localization and navigation:

1) Depth cameras typically generate voluminous data that cannot be processed in its entirety in real time for localization (e.g., the Microsoft Kinect sensor produces 9.2 million 3D pts/sec, compared to the 6800 2D pts/sec of the Hokuyo URG-04lx laser rangefinder).

2) Given that we already have existing 2D maps of our indoor environments, the observed 3D point clouds should be matched with the 2D maps.

In this paper, we tackle both these challenges. We first introduce the Fast Sampling Plane Filtering (FSPF) algorithm that samples the depth image to produce a set of points corresponding to planes, along with the plane parameters (normals and offsets). The volume of data to be processed is thus significantly reduced, addressing the first challenge with the additional advantage that non-planar objects in the scene, which are unlikely to correspond to map features are filtered. We then address the second challenge by introducing an observation model in our localization algorithm that matches the plane filtered points to the lines in the 2D maps, making it possible to reuse our existing 2D maps. This is in contrast to, and more effective than (as we shall show) down-projecting the 3D point cloud and binning it to simulate a conventional laser rangefinder. Our combined approach interestingly uses only the depth image and does not require the RGB images. The sampled points generated are also used to perform obstacle avoidance for navigation of the robot. Fig. 1 shows a snapshot of the key processed results after plane filtering, localization, and computing the obstacle avoidance margins.

Since our application is based on a ground robot, 6 degree of freedom (6D) localization is not required since the height of the sensor on the robot and its tilt and roll angles are fixed. At the same time, observations in 3D made by the depth camera has the potential to provide more useful information than planar laser rangefinders which sense objects only on a single 2D plane. Furthermore, typical indoor environments have an abundance of large planar features which are discernible in the depth images.
II. RELATED WORK

Approaches that operate on raw 3D point clouds for plane (and general geometric shape) detection [1], [2] are ill-suited to running in real-time due to their high computational requirements, and because they ignore the fact that depth cameras make observations in ‘2.5D’: the depth values are observed on a (virtual) 2D image plane originating from a single point. Region growing [3] exploits the local correlation in the depth image and attempts to assign planes to every 3D point. The Fast Sampling Plane Filtering algorithm, which we introduce in this paper, in contrast samples points at random and does not attempt to fit planes to every point, and instead uses local RANSAC [4].

There has been considerable work in 2D localization and mapping ([5] provides an overview of the recent advances in SLAM), and in using localization on 2D maps to generate 3D models using additional scans [6]. Specific to the problem of building 3D maps with 6 degrees of freedom (6D) localization is 6D SLAM [7], [8] that builds maps using 3D points in space, but these methods do not reason about the geometric primitives that the 3D points approximate.

An alternative approach to mapping using the raw 3D points is to map using planar features extracted from the 3D point cloud [9], [10]. In particular, 3D Plane SLAM [11] is a 6D SLAM algorithm that uses observed 3D point clouds to construct maps with 3D planes. The plane detection in their work relies on region growing [3] for plane extraction, whereas our approach uses sampling of the depth image. In addition, our observation model projects the observed planes onto the existing 2D vector map used for 2D laser rangefinder sensors.

More recently, techniques for 6D localization and mapping using RGB-D cameras have been explored. One such approach constructs surface element based dense 3D maps [12] which are simultaneously used for localizing in 3D using iterative closest point (ICP) as well as visual feature (SIFT) matching. While such approaches generate visually appealing results, they do not correspond to any planes. Algorithm 1 outlines the plane filtering procedure. It uses the helper subroutine [numInliers, \( \hat{P} \), \( \hat{R} \) ← RANSAC(\( d_0 \), \( w' \), \( h' \), \( l \), \( \epsilon \))], which performs the classical RANSAC algorithm over the window of size \( w' \times h' \) around location \( d_0 \) in the depth image, and returns inlier points and normals \( \hat{P} \) and \( \hat{R} \) respectively, as well as the number of inlier points found. The configuration parameters required by FSPF are listed in Table I.

FSPF takes the depth image \( I \) as its input, and creates a list \( P \) of \( n \) 3D points, a list \( R \) of corresponding plane normals, and a list \( O \) of outlier points that do not correspond to any planes. Algorithm 1 outlines the plane filtering procedure. It uses the helper subroutine [numInliers, \( \hat{P} \), \( \hat{R} \) ← RANSAC(\( d_0 \), \( w' \), \( h' \), \( l \), \( \epsilon \))], which performs the classical RANSAC algorithm over the window of size \( w' \times h' \) around location \( d_0 \) in the depth image, and returns inlier points and normals \( \hat{P} \) and \( \hat{R} \) respectively, as well as the number of inlier points found. The configuration parameters required by FSPF are listed in Table I.

FSPF proceeds by first sampling three locations \( d_0, d_1, d_2 \) from the depth image (lines 9-11). The first location \( d_0 \) is selected randomly from anywhere in the image, and \( d_1 \) and \( d_2 \) are selected randomly within a neighborhood of size \( \eta \) around \( d_0 \). The 3D coordinates for the corresponding points \( p_0, p_1, p_2 \) are then computed using eq. 1-3. A search window of width \( w' \) and height \( h' \) is computed based on the mean depth (z-coordinate) of the points \( p_0, p_1, p_2 \) (lines 14-16), and the minimum expected size \( S \) of the planes in the world.

III. FAST SAMPLING PLANE FILTERING

Depth cameras provide, for every pixel, color and depth values. This depth information, along with the camera intrinsics (horizontal field of view \( f_h \), vertical field of view \( f_v \), image width \( w \) and height \( h \) in pixels) can be used to reconstruct a 3D point cloud. Let the depth image of size \( w \times h \) pixels provided by the camera be \( I \), where \( I(i, j) \) is the depth of a pixel at location \( d = (i, j) \). The corresponding 3D point \( p = (p_x, p_y, p_z) \) is reconstructed using the depth value \( I(d) \) as

\[
p_x = I(d) \left( \frac{j}{w} - 0.5 \right) \tan \left( \frac{f_h}{2} \right),
\]

\[
p_y = I(d) \left( \frac{i}{h} - 0.5 \right) \tan \left( \frac{f_v}{2} \right),
\]

\[
p_z = I(d).
\]

With limited computational resources, most algorithms (e.g. localization, mapping etc.) cannot process the full 3D point cloud at full camera frame rates in real time. The naive solution would therefore be to sub-sample the 3D point cloud for example, by dropping (say) one out of three points, or sampling randomly. Although this reduces the number of 3D points being processed by the algorithms, it ends up discarding information about the scene. An alternative solution is to convert the 3D point cloud into a more compact, feature-based representation, like planes in 3D. However, computing optimal planes to fit the point cloud for every observed 3D point would be extremely CPU-intensive and sensitive to occlusions by obstacles which exist in real scenes. The Fast Sampling Plane Filtering (FSPF) algorithm combines both ideas: it samples random neighborhoods in the depth image, and in each neighborhood, it performs a RANSAC based plane fitting on the 3D points. Thus, it reduces the volume of the 3D point cloud, it extracts geometric features in the form of planes in 3D, and it is robust to outliers since it uses RANSAC within the neighborhood.

FSPF takes the depth image \( I \) as its input, and creates a list \( P \) of \( n \) 3D points, a list \( R \) of corresponding plane normals, and a list \( O \) of outlier points that do not correspond to any planes. Algorithm 1 outlines the plane filtering procedure. It uses the helper subroutine [numInliers, \( \hat{P} \), \( \hat{R} \) ← RANSAC(\( d_0 \), \( w' \), \( h' \), \( l \), \( \epsilon \))], which performs the classical RANSAC algorithm over the window of size \( w' \times h' \) around location \( d_0 \) in the depth image, and returns inlier points and normals \( \hat{P} \) and \( \hat{R} \) respectively, as well as the number of inlier points found. The configuration parameters required by FSPF are listed in Table I.

FSPF proceeds by first sampling three locations \( d_0, d_1, d_2 \) from the depth image (lines 9-11). The first location \( d_0 \) is selected randomly from anywhere in the image, and \( d_1 \) and \( d_2 \) are selected randomly within a neighborhood of size \( \eta \) around \( d_0 \). The 3D coordinates for the corresponding points \( p_0, p_1, p_2 \) are then computed using eq. 1-3. A search window of width \( w' \) and height \( h' \) is computed based on the mean depth (z-coordinate) of the points \( p_0, p_1, p_2 \) (lines 14-16), and the minimum expected size \( S \) of the planes in the world.
Local RANSAC is then performed in the search window. If more than \( \alpha_{in} \) inlier points are produced as a result of running RANSAC in the search window, then all the inlier points are added to the list \( P \), and the associated normals to the list \( R \). This algorithm is run a maximum of \( m_{max} \) times to generate a list of maximum \( n_{max} \) 3D points and their corresponding plane normals. Fig. 2 shows an example scene with the plane filtered points and their corresponding plane normals.

### IV. LOCALIZATION

For the task of localization, the plane filtered point cloud \( P \) and the corresponding plane normal estimates \( R \) need to be related to the 2D map. The 2D map representation which we use is a “vector” map: it represents the environment as a set of line segments (corresponding to the obstacles in the environment), as opposed to the more commonly used occupancy grid [13] based maps. The observation model therefore has to compute the line segments likely to be observed by the robot given its current pose and the map. This is done by an analytic ray cast step. We therefore introduce next the representation of the 2D vector map and the algorithm for analytic ray casting using the 2D vector map.

### A. Vector Map Representation and Analytic Ray Casting

The map \( M \) used by our localization algorithm is a set of \( s \) line segments \( l_i \) corresponding to all the walls in the environment: \( M = \{l_i\}_{i=1}^s \). Such a representation may be acquired by mapping (e.g. [14]) or (as in our case) taken from the blueprints of the building.

Given this map, to compute the observation likelihoods based on observed planes, the first step is to estimate which lines on the map are likely to be observed (the “scene lines”), given the pose estimate of the robot. This ray casting step is analytically computed using the vector map representation.

The procedure to analytically generate a ray cast at location \( x \) given the map \( M \) is outlined in Algorithm 2. The returned result is the scene lines \( L \): a list of non-intersecting, non-occluded line segments visible by the robot from the location \( x \). This algorithm calls the helper procedure \( \text{TrimOcclusion}(x, l_1, l_2, L) \) that accepts a location \( x \), two lines \( l_1 \) and \( l_2 \), and a list of lines \( L \). \( \text{TrimOcclusion} \) trims line \( l_1 \) based on the occlusions due to the line \( l_2 \) as seen from the location \( x \). The list \( L \) contains lines that yet need to be tested for occlusions by \( l_2 \). There are in general 4 types of arrangements of \( l_1 \) and \( l_2 \), as shown in Fig. 3:

1. \( l_1 \) is not occluded by \( l_2 \). In this case, \( l_1 \) is unchanged.
2. \( l_1 \) is completely occluded by \( l_2 \). \( l_1 \) is trimmed to zero length by \( \text{TrimOcclusion} \).
3. \( l_1 \) is partially occluded by \( l_2 \). \( l_1 \) is first trimmed to a non occluded length, and if a second disconnected non occluded section of \( l_1 \) exists, it is added to \( L \).
4. \( l_1 \) intersects with \( l_2 \). Again, \( l_1 \) is first trimmed to an non occluded length, and if a second disconnected non occluded section of \( l_1 \) exists, it is added to \( L \).

### Table I: Configuration parameters for FSPF

![Fig. 2. Fast Sampling Plane Filtering in a scene with a cluttered desktop. The complete 3D point cloud is shown on the left, the plane filtered points and their corresponding normals on the right. The table clutter is rejected by FSPF while preserving the large planar elements like the monitors, the table surface, the walls and the floor.](image-url)
Fig. 3. Line occlusion cases. Line $l_1$ is being tested for occlusion by line $l_2$ from location $x$. The occluded parts of $l_1$ are shown in green, and the visible parts in red. The visible ranges are bounded by the angles demarcated by the blue dashed lines.

**Algorithm 2** Analytic Ray Cast Algorithm

```
1: procedure ANALYTICRAYCAST($M$, $x$)
2:   $\hat{L} \leftarrow M$
3:   $L \leftarrow \{\}$
4:   for $l_i \in \hat{L}$ do
5:     for $l_j \in L$ do
6:       TrimOcclusion($x$, $l_i$, $l_j$, $\hat{L}$)
7:     end for
8:     if $||l_i|| > 0$ then $\triangleright$ $l_i$ is partly non occluded
9:       for $l_j \in L$ do
10:      TrimOcclusion($x$, $l_j$, $l_i$, $\hat{L}$)
11:     end for
12:   end if
13: end for
14: return $L$
15: end procedure
```

The analytic ray casting algorithm (Algorithm 2) proceeds as follows: A list $L$ of all possible lines is made from the map $M$. Every line $l_i \in \hat{L}$ is first trimmed based on occlusions by lines in the existing scene list $L$ (lines 5-7). If at least part of $l_i$ is left non occluded, then the existing lines in $\hat{L}$ are trimmed based on occlusions by $l_i$ (lines 9-11) and $l_i$ is then added to the scene list $L$. The result is a list of non occluded, non-intersecting scene lines in $L$. Fig. 4 shows an example scene list on the real map.

Thus, given the robot pose, the set of line segments likely to be observed by the robot is computed. Based on this list of line segments, the actual observation of the plane filtered point cloud $P$ is related to the map using the projected 3D point cloud model, which we introduce next.

**B. Projected 3D Point Cloud Observation Model**

Since the map on which the robot is localizing is in 2D, the 3D filtered point cloud $P$ and the corresponding plane normals $R$ are first projected onto 2D to generate a 2D point cloud $P'$ along with the corresponding normalized normals

Fig. 4. Analytically rendered scene list. The lines in the final scene list $L$ are shown in red, the original, untrimmed corresponding lines in green, and all other lines on the map in blue.

$R'$. Points that correspond to ground plane detections are rejected at this step. Let the pose of the robot $x$ be given by $x = \{x_1, x_2\}$ where $x_1$ is the 2D location of the robot, and $x_2$ its orientation angle. The observable scene lines list $L$ is computed using an analytic ray cast. The observation likelihood $p(y|x)$ (where the observation $y$ is the 2D projected point cloud $P'$) is computed as follows:

1) For every point $p_i$ in $P'$, line $l_i$ ($l_i \in L$) is found such that the ray in the direction of $p_i - x_1$ and originating from $x_1$ intersects $l_i$.

2) Points for which no such line $l_i$ can be found are discarded.

3) Points $p_i$ for which the corresponding normal estimates $r_i$ differ from the normal to the line $l_i$ by a value greater than a threshold $\theta_{max}$ are discarded.

4) The perpendicular distance $d_i$ of $p_i$ from the (extended) line $l_i$ is computed.

5) The total (non-normalized) observation likelihood $p(y|x)$ is then given by:

$$p(y|x) = \prod_{i=1}^{n} \exp\left[-\frac{d_i^2}{2f\sigma^2}\right]$$ (4)

Here, $\sigma$ is the standard deviation of a single distance measurement, and $f : f > 1$ is a discounting factor to discount for the correlation between rays. The observation likelihoods thus computed are used for localization using the Corrective Gradient Refinement (CGR) [15] algorithm, which we review in brief.

**C. Corrective Gradient Refinement for Localization**

The belief of the robot’s location is represented as a set of weighted samples or “particles”, as in Monte Carlo Localization (MCL)[16]: $Bel(x_t) = \{x_t^i, w_t^i\}_{i=1}^{m}$. The CGR algorithm iteratively updates the past belief $Bel(x_{t-1})$ using observation $y_t$ and control input $u_{t-1}$ as follows:

1) Samples of the belief $Bel(x_{t-1})$ are evolved through the motion model, $p(x_t|x_{t-1}, u_{t-1})$ to generate a first stage proposal distribution $q^0$.

2) Samples of $q^0$ are “refined” in $r$ iterations (which produce intermediate distributions $q^i$, $i \in [1, r-1]$)
using the gradients $\frac{\partial}{\partial x}p(y_i|x)$ of the observation model $p(y_i|x)$.

3) Samples of the last generation proposal distribution $q^r$ and the first stage proposal distribution $q^0$ are sampled using an acceptance test to generate the final proposal distribution $q$.

4) Samples $x_i$ of the final proposal distribution $q$ are weighted by corresponding importance weights $w_i$, and resampled with replacement to generate $Bel(x_1)$.

Therefore, for CGR we need to compute both the observation likelihood, as well as its gradients. The observation likelihood is computed using Eq. 4, and the corresponding gradients are therefore given by,

$$\frac{\delta}{\delta x}p(y|x) = -\frac{p(y|x)}{f\sigma^2} \sum_{i=1}^{n} \left[ \delta d_i \frac{\delta d_i}{\delta x} \right]. \quad (5)$$

The term $\frac{\delta d_i}{\delta x}$ in this equation has two terms, corresponding to the translation component $\frac{\delta d_i}{\delta x}$ and the rotational component $\frac{\delta d_i}{\delta x}$. These terms are computed by rigid body translation and rotation of the point cloud $P$ respectively.

The observation likelihoods and their gradients thus computed are used to update the localization using CGR.

V. Navigation

For the robot to navigate autonomously, it needs to be able to successfully avoid obstacles in its environment. This is done by computing open path lengths available to the robot for different angular directions. Obstacle checks are performed using the 3D points from the sets $P$ and $O$. Given the robot radius $r$ and the desired direction of travel $\theta_d$, the open path length $d(\theta)$ as a function of the direction of travel $\theta$, and hence the chosen obstacle avoidance direction $\theta^*$ are calculated as:

$$P_B = \left\{ p : p \in P \cup O \wedge ||p - p \cdot \hat{\theta}|| < r \right\} \quad (6)$$

$$d(\theta) = \min_{p \in P_B} \left( \max(0, ||p \cdot \hat{\theta}|| - r) \right) \quad (7)$$

$$\theta^* = \arg \max_{\theta} \left( d(\theta) \cos(\theta - \theta_d) \right) \quad (8)$$

Here, $\hat{\theta}$ is a unit vector in the direction of the angle $\theta$, and the origin of the coordinate system is coincident with the robot’s center. Fig. 5 shows an example scene with two tables and four chairs that are detected by the depth camera. Despite randomly sampling (with a maximum of 2000 points) from the depth image, all the obstacles are correctly detected, including the table edges. The computed open path lengths from the robot location are shown by red boxes.

VI. Experimental Results

We evaluated the performance of our depth camera based localization and navigation algorithms over two sets of experiments. The first set of experiments compare our approach using FSPF CGR localization to three other approaches that use the Kinect for localization by simulating laser range finder scans from the Kinect sensor. The second set of long run trials test the effectiveness of our complete localization and navigation system over a long period of time.

Our experiments were performed on our custom built omnidirectional indoor mobile robot, equipped with the Microsoft Kinect sensor. The Kinect sensor provides depth images of size $640 \times 480$ pixels at 30Hz. To compare the accuracy in localization of the different approaches using the Kinect, we also used a Hokuyo URG-04LX 2D laser rangefinder scanner as a reference. The autonomous long run trials were run using the Kinect alone for localization and navigation. All trials were run single threaded, on a single core of an Intel Core i7 950 processor.

A. Comparison of FSPF to Simulated Laser Rangefinder localization

We compared our approach using FSPF CGR localization to the following three other CGR based laser range finder localization algorithms where the data from the Kinect sensor was used to simulate laser range finder scans:

1) Extracting a single raster line from the Kinect depth image, reconstructing the corresponding 3D points, and

![Fig. 5. Obstacle avoidance: The raw 3D point cloud (a) and (b) the sampled points (shown in color), along with the open path limits (red boxes). The robot location is marked by the axes.](image-url)
then down-projecting into 2D to generate the simulated laser rangefinder scans. We call this approach the Kinect-Raster (KR) approach.

2) Randomly sampling locations in the Kinect depth image, and using the corresponding 3D points to simulate the laser rangefinder scan. We call this approach the Kinect-Sampling (KS) approach.

3) Reconstructing the full 3D point cloud from the entire Kinect depth image, and using all these points to generate the simulated laser rangefinder scan. We call this approach the Kinect-Complete (KC) approach.

For estimating the error in localization using the Kinect, we used the localization estimates produced by the laser rangefinder CGR localization algorithm for reference. In the KR, KS and KC approaches, the simulated laser rangefinder scan had a simulated angular range of 180° and an angular resolution of 0.35°, although only part of this scan was populated with useful information due to the limited angular field of view of the Kinect. The number of points sampled in the KS approach was limited to 2000 points, the same as the number of plane filtered points generated in the FSPF approach.

We recorded a log with odometry and data from the Kinect sensor and the laser rangefinder while traversing a path consisting of corridors as well as open areas with unmapped obstacles. There was significant human traffic in the environment, with some humans deliberately blocking the path of the robot. This log was replayed offline for the different localization approaches, running 100 times per approach, with randomly added 20% noise to the odometry data. Fig. 6 shows the combined traces of the localization estimates for all the successful trials of each of the approaches. A trial was said to be “successful” if the error in localization was less than 1m at every timestep of the trial.

Fig. 8 shows a cumulative histogram of the error in localization using the different approaches. The FSPF approach has significantly less error than the other three approaches. Fig. 7 shows the cumulative failure rate as a function of elapsed run time. The FSPF approach has a 2% failure rate at the end of all the trials, whereas all the other approaches start failing after around 20s into the trials. The KR, KS, and KC approaches have total failure rates of 82%, 62% and 61% respectively. The abrupt increase in failures around the 20s mark corresponds to the time when the robot encounters unmapped objects in the form of humans, tables and chairs in an open area.

To compare the execution times of the different approaches, we kept track of the time taken to process all the Kinect depth image observations, and calculated the ratio of these execution times to the total duration of the trials. These values are thus indicative of the mean CPU processing load while running the algorithms online on the robot in real time. The values for the different algorithms were 0.01%, 3.6%, 56.6% and 16.3% respectively for the KR, KS, KC, and FSPF approaches respectively. It should be noted that since the KR, KS and KC approaches use simulated laser rangefinder scans with a fixed (180) number of rays, while the FSPF algorithm uses as many plane filtered points as are detected up to a maximum of \( n_{\text{max}} \), which we set to 2000 for the experiments.

**B. Long Run Trials**

To test the robustness of the depth-camera based FSPF localization and navigation solution, we set a series of random waypoints for the robot to navigate to, spread across the map. The total length of the path was just over 4km. Over the duration of the experiment, only the Kinect sensor was used for localization and obstacle avoidance. The robot successfully navigated to all waypoints, but localization had to be reset at three locations, which were in open areas of the map with unmapped obstacles where Kinect sensor could not observe any walls for a while. Fig. 9 shows the trace of
the robot’s location over the course of the experiment. We continue to use the FSPF localization and obstacle avoidance algorithms during daily deployments of our robot.

VII. CONCLUSION AND FUTURE WORK

In this paper, we introduced an algorithm for efficient depth camera based localization and navigation for indoor mobile robots. We introduced the Fast Sampling Plane Filtering algorithm to filter depth images into point clouds corresponding to local planes. We subsequently contributed an observation model that matches the plane filtered points to lines in the existing 2D maps for localization. Both the plane filtered, as well as the outlier point clouds are further used for obstacle avoidance. We experimentally showed FSPF localization to be more accurate as well as more robust compared to localization using Kinect based simulated laser rangefinder readings. We further demonstrated a long run trial of the robot autonomously operating for over 4km using the depth camera alone.

For use on other platforms like UAVs, scaling up the state space to full 6 degrees of freedom is another possible avenue of future work.

REFERENCES
