ABSTRACT

We report the first detection of the ground-state rotational transition of the methylidyne cation CH$^+$ towards the massive star-forming region DR 21 with the HIFI instrument onboard the Herschel satellite. The line profile exhibits a broad emission line, in addition to two deep and broad absorption features associated with the DR 21 molecular ridge and foreground gas. These observations allow us to determine a $^{12}$CH$^+$ J=1–0 line frequency of $\nu = 835\text{137} \pm 3 \text{ MHz}$, in good agreement with a recent experimental determination. We estimate the CH$^+$ column density to be a few $10^{13} \text{ cm}^{-2}$ in the gas seen in emission, and $> 10^{14} \text{ cm}^{-2}$ in the components responsible for the absorption, which is indicative of a high line of sight average abundance $|\text{CH}^+|/|\text{H}| > 1.2 \times 10^{-6}$. We show that the CH$^+$ column densities agree well with the predictions of state-of-the-art C-shock models in dense UV-illuminated gas for the emission line, and with those of turbulent dissipation models in diffuse gas for the absorption lines.

Key words. Astrochemistry - ISM : molecules - ISM : kinematics and dynamics - Turbulence

1. Introduction

The methylidyne ion CH$^+$ was among the first molecules to be detected in the interstellar medium (ISM)\cite{Douglas1941}. This reactive ion is prevalent in the diffuse ISM with column densities several orders of magnitude above the predictions of UV-driven equilibrium models (see references in\cite{Godard2009}). Apart from the strong emission lines of CH$^+$ detected in both the envelope of the Red Rectangle\cite{Hobbs2004} and NGC 7027\cite{Cernicharo1997}, all other observations are absorption lines detected at visible wavelengths in the spectra of nearby stars. CH$^+$ is a light molecule and its rotational lines lie at submillimeter and far infrared wavelengths. The exact frequencies of the rotational transitions of CH$^+$ have remained elusive for a long time because of the extreme reactivity of CH$^+$ and the difficulty in isolating it in the laboratory\cite{Pearson2006}. Recent laboratory measurements have led to $\nu = 835.137498(20) \text{ GHz}$ for the ground-state transition (Amano, 2010). Ground-based astronomical detection of $^{12}$CH$^+$(1-0) is prevented by its proximity to a strong atmospheric line of water vapor. It has been detected at the Caltech Submillimeter Observatory towards several massive star-forming regions of the inner Galaxy (Falgarone et al. in prep.,\cite{Falgarone2005}). The $^{12}$CH$^+$ abundances averaged along these long lines-of-sight (los), confirm the high abundances of this species inferred from visible observations in the local ISM, $|\text{CH}^+|/|\text{H}| \sim 8 \times 10^{-9}$ on average. In this paper, we report the detection of the $^{12}$CH$^+$ J=1–0 transition towards the massive star-forming region DR21, presented in Sect. 2. The HIFI observations are described in Sect. 3. The results, given in Sect. 4, are compared to models in Sect. 5.

2. The DR 21 region

The massive star-forming region DR 21 is located in the Cygnus X complex at an average distance of 1.7 kpc, that of the Cyg OB2 stellar association (see reviews by\cite{Jakob2007};\cite{Schneider2010}). The DR 21 molecular core is one of the most massive cores in the Galaxy ($2.5 \times 10^5 \text{ M}_\odot$ at the 1 pc-scale)\cite{Kirby2009}. It is located in front of the main DR 21 HH region comprising five compact HH regions and more diffuse ionised gas\cite{Reilfsena1989},\cite{Wilson1998},\cite{Cyganowski2003}.

The star-forming region DR 21 itself is known to host one of the most powerful molecular outflows shining in vibrationally excited H$_2$ (e.g.,\cite{Garden1992}). The outflow source is heavily extinguished by more than 100 magnitudes, and its location is not accurately known\cite{Wilson1995}. High velocity HI (up to 90 kms$^{-1}$) associated with the molecular outflow has been detected by the VLA\cite{Russell1992}, indicating that the molecular outflow may be driven by this atomic jet. The outflow shows up as broad wings in CO and HCO$^+$ lines\cite{Kirby2009}. At the position of the HIFI beam, the $v = 1 - 0 \text{ S(1)}$ H$_2$ emission line has a similar broad width\cite{Nadeau1988};\cite{Cruz-Gonzalez2007} to that of the SiO emission\cite{Motte2007}.

Some line profiles imply that there is foreground gas, which is probably associated with the Cygnus X complex\cite{Jakob2007};\cite{Schneider2010}. A foreground component associated with W75N shows up as weak emission lines at $v_{\text{LSR}} \sim 8 \text{ km s}^{-1}$ in low excitation transitions of CO and HCO$^+$ or atomic carbon, and in the atomic oxygen fine-structure line, with $N(\text{O}) > 5 \times 10^{18} \text{ cm}^{-2}$\cite{Poglitsch1996}. The total hydro-
gen column density of this foreground material is estimated to be $N(\text{H}) \sim 1.4 \times 10^{22} \text{ cm}^{-2}$ for an elemental abundance ratio $[\text{O}]/[\text{H}] = 3.45 \times 10^{-4}$ (Oliveira et al. 2003), in coherence with $N(\text{H}) = (1.3 \pm 0.4) \times 10^{22} \text{ cm}^{-2}$ inferred from K extinction to DR21 (Marshall et al. 2006). This component is also detected in atomic hydrogen, where $N(\text{H})$ is known to be $\sim 1.5 \times 10^{21} \text{ cm}^{-2}$.

### 3. HIFI observations

All FIR spectra presented here were obtained in the course of performance verification observations with the HIFI instrument (Pilbratt et al. 2010; de Graauw et al. 2010). Since their main goal was to demonstrate the functionality and performance of the different observing modes, the spectra were taken with a large variety of observing strategies. Most observations were only single-point observations towards the central position of the DR21 HII region at RA=20h39m01.1s, Dec=42°19'43.0" (J2000). At the frequencies around 1 THz discussed here, the HIFI beam covers about 20" HPBW (or 0.16 pc at 1.7 kpc). Here, we only present data from the wideband spectrometer (WBS) that provides a resolution of 1.1 MHz, corresponding to 0.2 km/s (at 1900 GHz) and 0.4 km/s (at 835 GHz).

The CH$^+$ spectrum at 835 GHz was obtained in a single-point load-chop observing mode without OFF reference. It uses the internal cold load as reference, having the advantage that we can exclude any self-chopping effects in the line profiles. The mode has, however, the disadvantage that the different optical paths towards the sky and the internal calibration load sometimes lead to standing wave differences that are detected as baseline ripples. We subtracted these manually using the HifiFitFringe pipeline tool. The total integration time on the source was 48 s leading to a noise level of 0.1 K for the combination of the spectra from both polarisations at the WBS resolution.

The H$_2$O 1$_{11}$−0$_{00}$ (1113 GHz) line was observed in the frame of a spectral scan in a load-chop mode and an on-source integration time of 30 s. The baseline was calibrated on a distant OFF position (20h37m10s, 42°37'00") because the first selected OFF position, closer to the ON, retained some signal (see Fig. 1). The [CII] line was detected in one of the first double-beam switch raster mapping observations in which neither the logic of the mapping mode worked as expected nor the pointing of the instrument was yet known. The instrument pointing was measured afterwards and the map coordinates were corrected by hand to include the correct offsets. A comparison of the integrated [CII] intensities in the shifted map with the MSX 8 µm band shows a very good agreement, confirming the accuracy of the correction. The observations were taken on a 7" raster that included a 14 s on-source integration time at each point. To obtain a spatial resolution comparable to that of the other two lines, the map was convolved with a Gaussian beam of 20" at the DR 21 central position.

### 4. Results of the line profile analysis

The HIFI spectra are displayed in Fig. 1 with, for comparison, an IRAM-30m spectrum of HCO$^+$ (1-0) (Schneider et al. 2010). The line profiles exhibit both complex emission and absorption because of the multiplicity of velocity components and gas physical conditions within the beam. The line integrated areas in emission and absorption are remarkably comparable. This would lead to a weak or non-detection with low spectral resolution instruments. The dashed lines in the CH$^+$ and H$_2$O spectra, at about half the continuum level, reveal the broad velocity ranges across which the absorption lines are saturated.

The CH$^+$ (1-0), C$^+$ and p-H$_2$O spectra, plotted after their continuum has been subtracted, are superimposed on the frequency of the CH$^+$ 1−0 line set to 835.137 GHz. We propose in Sect. 5 that the broad line emission originates from a shock associated with the outflow, and we show that the three species, CH$^+$, C$^+$, and H$_2$O are connected with each other in the...
shock chemistry. The good agreement (within ± 1 km s\(^{-1}\)) between the blue wing of the emission profile lines of these three species allows us to adopt \(v = 835137 \pm 3\) MHz as the rest frequency of the \(^{12}\)CH\(^+\)(1-0) line, which is remarkably consistent with the experimental value measured by Amano (2010).

The CH\(^+\) J=1-0 line profile can be decomposed into a broad emission line series and a series of absorption features. We used information from the line profiles of CO and HCO\(^+\) J=1-0 (see Fig. [1]), the spectra of atomic carbon Jakob et al. (2007), and other HIFI spectra Ossenkopf et al. (2010), van der Tak et al. (2010) to constrain the velocity and linewidth of these components. Since the CH\(^+\) line has not been observed, the actual CH\(^+\) emission profile is unknown. We had to rely on the symmetric shapes of the CO emission lines to model the broad emission wings with Gaussians adjusted on the blue wings of the lines (Table 1). Over the velocity range -5 to 17 km s\(^{-1}\), not only the continuum level but also the core line emission is absorbed by intervening gas. The broad emission lines (Δv = 20 km s\(^{-1}\), see Table 1) correspond to the emission associated with the outflow shock (see Sect. 5). A still broader component in the [CII] line has a width similar to that of the H66α recombination lines Roelfsema et al. (1989). Self-absorption features in the range \(-3\) to 2 km s\(^{-1}\), caused by the close environment of the DR21 core, are visible in CO, HCO\(^+\)(4-3), and other dense gas tracers (e.g., NH\(_3\) inversion lines). The absorption dip at this velocity is more prominent in the H\(_2\)O(1,1 – 0,0) profile as expected from the high critical density of this transition. We disregarded this velocity range in our analysis because of the unknown line intensity of the dense core emission. In contrast, the absorption at \(v > 7\) km s\(^{-1}\) corresponds to the gas that is most likely to be associated with the W75N cloud in the Cygnus X complex. Its velocity coverage is very similar in the CH\(^+\) and C\(^+\) spectra. We fitted three components in this velocity range, guided by the absorption features of the HCO\(^+\) J=1-0 and H\(_2\)O profiles at \(v_{LSR} = 7.5, 11,\) and 13.7 km s\(^{-1}\) shown in Fig. 1, the resulting profiles being in red.

The CH\(^+\) column density of the emission line was determined by assuming that it is optically thin. This is consistent with the \(^{13}\)CH\(^+\)(1-0) line not being detected in emission towards galactic massive star-forming regions (Falgarone et al. in prep., Falgarone et al. 2005). The total CH\(^+\) column density was therefore assumed to scale with the line integrated area (in K km s\(^{-1}\)) with a coefficient that depends on the excitation temperature. For 40 K < \(T_{ex} < 100\) K, the range of \(T_{ex}\) that minimizes \(N(\text{CH}^+)\), a lower limit \(N_{min}(\text{CH}^+) = 7 \times 10^{11}\) cm\(^{-2}\) \(\int T(v)dv\) was obtained, using the spontaneous decay rate \(A_{10} = 5.9 \times 10^{-3}\) s\(^{-1}\) inferred from the dipole moment, \(\mu = 1.62\) D Kobayashi et al. (1993). In absorption, we inferred the column density from the integral of the optical depth (in km s\(^{-1}\)) to be \(N_{\text{abs}}(\text{CH}^+) = 3.3 \times 10^{12}\) cm\(^{-2}\) \(\int \tau(v)dv\). It is almost independent of \(T_{ex}\) as long as \(T_{ex} << h
u/k\) is \(39\) K, an approximation that is valid for gas of density much lower than the critical density of the transition (\(> 10^6\) cm\(^{-3}\)) and not closely associated with intense FIR radiation. The resulting CH\(^+\) column densities are given in Table 2.

Those of the saturated absorption components are lower limits. Although the Gaussian decomposition is by no means unique, it provides an estimate of both the detected column densities and the CH\(^+\) abundance relative to the total hydrogen \([\text{CH}^+]/[\text{H}] > 1.2 \times 10^{-8}\) in the diffuse gas. We note that the [CII] line opacity of the foreground gas, averaged over 10 km s\(^{-1}\), is \(\tau_{[\text{CII}]} > 1.8\). This opacity limit corresponds to a C\(^+\) column density larger than \(2 \times 10^{18}\) cm\(^{-2}\) for gas of density lower than the critical density of the transition \(n_{cr}(\text{C}^+)\), i.e. \(n > n_{cr}(\text{C}^+)\). From the estimated gas column of \(1.4 \times 10^{22}\) cm\(^{-2}\), the expected C\(^+\) column is \(2 \times 10^{18}\) cm\(^{-2}\), assuming a gas-phase carbon abundance of \(1.4 \times 10^{-4}\). This value is in close agreement with that derived for the low density limit, strengthening the association of the foreground absorption with gas of densities lower than \(n > 10^2\) cm\(^{-3}\).

5. Comparison with model predictions

The only formation route of the molecular ion CH\(^+\) is understood to be initiated by the reaction C\(^+\) + H\(_2\) \(\rightarrow\) CH\(^+\) + H, which is highly endothermic (\(\Delta\epsilon/E\) =4640 K). The formation of CH\(^+\) in the cold interstellar medium therefore requires suprathermal energy. Several scenarios have been investigated: C-shocks (Pineau des Forêts et al. 1986 (C)), highly illuminated and dense photon-dominated regions (PDR) where C\(^+\) reacts with vibrationally excited H\(_2\) (Stenberq & Delagrange 1995, Aguînez et al. 2010), turbulent interfaces between the warm and cold neutral medium (Lesaffre et al. 2007), and regions of intermittent turbulent dissipation (TDR models, Godard et al. 2009). In the first and last models, ion-neutral friction plays a major role.

For the DR 21 core, it is unclear which processes are at work in the CH\(^+\) formation. Broad (\(\Delta v = 20\) km s\(^{-1}\)) emission lines of SiO Motte et al. (2007), [CII] Cruz-Gonzalez et al. (2007), and similar to the broad emission in the HIFI profiles, are observed and suggest the influence of a shock. We now present a preliminary attempt to account for the observed column densities of CH\(^+\) in this highly irradiated environment.

5.1. CH\(^+\) emission line: C-shock models

We used a steady-state model for C-shocks with time-dependent chemistry and ionization (Flower & Pineau des Forêts 2003). The chemical network was supplemented with the relevant photo-reactions (Pineau des Forêts, priv. comm.). The H\(_2\) and CO self-shielding were assumed to be those of a PDR model at \(n_H = 10^3\) cm\(^{-3}\). We adopted a pre-shock density \(n_H = 10^4\) cm\(^{-3}\), a shock velocity \(v_s = 20\) km s\(^{-1}\), a magnetic field \(B = 20\) \(\mu\)G (from the measure of magnetic field in Roberts et al. 1997), and a standard cosmic-ray ionisation rate of \(\zeta = 5 \times 10^{-17}\) s\(^{-1}\). We stopped the computation of the shocks at a neutral flow time of \(10^7\) yr, which corresponds to the estimated dynamical age of the outflow (lobes of 0.5 pc for a jet velocity up to 100 km s\(^{-1}\)). The CH\(^+\) column-density was found to have already reached a

</table>
plateau at this stage in the shock, so the CH⁺ results are insensitive to that choice of age.

Although the incident radiation field is estimated to be $\chi = 10^5$ in ISRF units (Ossenkopf et al. 2010) for the material closest to the HII region, we keep this value as a free parameter. Figure 3 displays the total column densities of CH⁺ and H₂O as a function of the adopted external radiation field. Its effect turns out to be quite interesting: a strong radiation field ($\chi > 10^5$) is needed to account for the large observed CH⁺ column density. It is the enhanced photo-dissociation of CH₃⁺ and CH₂⁺, both products of the rapid hydrogenation of CH⁺ in the shock, that increases the abundance of CH⁺ as $\chi$ increases. The shock model also predicts that both CH⁺ and H₂O are rather well distributed across the various velocity slices of the shock. This supports the assumption that the CH⁺ and H₂O blue line wings are similar, underlying the CH⁺ line frequency determination.

5.2 CH⁺ absorption lines: turbulent dissipation models

The large CH⁺ column density observed in the foreground component corresponds to a $los$ average of the CH⁺ abundance, $[\text{CH}⁺]/[\text{H}⁺]_{\text{line}} > 1.2 \times 10^{-6}$, for $N(\text{H}) = 1.4 \times 10^{22}$ cm⁻² (see Sect. 2). It can be reproduced in the framework of TDR models. At any time, a very large number of tiny regions ($I \sim 100$ AU), altogether filling a small fraction of the entire $los$, are developing a transient warm chemistry triggered by dissipation bursts where local CH⁺ abundances reach $10^{-6}$ (Godard et al. 2009). The filling factor of the ensemble of these tiny structures is set by the energy transfer rate in the turbulent cascade, $\epsilon = \rho v^3 l_i$, identified with the turbulent dissipation rate. The resulting average abundance is found to scale as $[\text{CH}⁺]/[\text{H}⁺]_{\text{line}} \approx 6.4 \times 10^{-6} (\epsilon/\rho_0(n_H/50$ cm⁻³)⁻² for an ambient radiation field $\chi = 3$ in ISRF units, where $n_H$ is the density of the gas in which the bursts occur and $\epsilon$ is a non-local quantity of galactic average $\epsilon_0 = 2 \times 10^{-25}$ erg cm⁻³s⁻¹ (see Godard et al. 2009). Fluctuations by two orders of magnitude are observed in the ISM about that galactic average, the highest values being reached in active star-forming regions, such as Cygnus X. We thus expect $\epsilon$ to be up to 100 times higher than average in Cygnus X, so that the observed CH⁺ abundance can be produced by intermittent dissipation of turbulence occurring in gas density up to ~250 cm⁻³. The total number of tiny structures along that 1.7 kpc $los$ is found to scale as $\sim 3.5 \times 10^3 (\epsilon/\rho_0(n_H/50$ cm⁻³)⁻².

6. Conclusion

We have detected the line profile of CH⁺(1-0) towards the DR 21 massive star-forming region with the HIIF instrument, obtaining several major results. The line is a combination of broad emission and almost saturated broad absorption, which have comparable integrated areas. The rest-frame frequency of the CH⁺(1-0) line is inferred to be $v = 835137 \pm 3$ MHz. For the gas seen in emission, the CH⁺ column density, of about $10^{13}$ cm⁻², compares well to predictions of C-shock models propagating in dense, highly illuminated gas. Additional chemical modeling (and radiative transfer calculations) are needed to confirm the C-shock framework and exploit the other line signatures. The large CH⁺ column density in the foreground gas, $N(\text{CH}⁺) \sim 10^{14}$ cm⁻², can be explained by the turbulent dissipation models in diffuse gas and confirms the large opacity of that line in the diffuse molecular gas.

Acknowledgements. HIIF has been designed and built by a consortium of institutes and university departments from across Europe, Canada and the United States (NASA) under the leadership of SRON, Netherlands Institute for Space Research, Groningen, The Netherlands, and with major contributions from Germany, France and the US. Consortium members are: Canada: CSA, U. Waterloo, France: CESR, LAB, LERMA, IRAM; Germany: KOSMA, MPIfR, MPS; Ireland: NUI Maynooth; Italy: ASI, IFSI-INAF; Observatorio Astrofísico de Arcetri-INAF; Netherlands: SRON, TUD, Poland: CAMK, CBK; Spain: Observatorio Astronómico Nacional (IGN), Centro de Astrobiología; Sweden: Chalmers University of Technology - MC2, RSS & GARD, Onsala Space Observatory, Swedish National Space Board, Stockholm University - Stockholm Observatory; Switzerland: ETH Zurich, FHNW; USA: CalTech, JPL, NHSC. MG and EF acknowledge the support from the Centre National de Recherche Spatiale (CNES). Part of this work was supported by the German DeutschenFor- schungsgemeinschaft, DFG project SOn71/1–1. We thank G. Pineau des Forêts for providing us with his version of the code for C-shock models.
